A key event in early vertebrate evolution was the transition from a sessile, filter-feeding lifestyle to one of active predation. This event was driven, in large part, by a transformation of the ancestral chordate pharynx, resulting in the vertebrate 'new head' (Forey and Janvier, 1994; Gans and Northcutt, 1983; Northcutt, 2005; Northcutt and Gans, 1983).

In addition, we have studied the evolution of the related TIMP gene family and identify a single ciona and four zebrafish TIMP genes. The complexity seen in the vertebrate metzincin gene families was mainly acquired during vertebrate evolution. The metzincin gene repertoire in protostomes and invertebrate deuterostomes has remained relatively stable.

SUMMARY. Attainment of the biting jaw is regarded as one of the major novelties in the early history of vertebrates. Based on a comparison between lamprey and gnathostome embryos, evolutionary developmental studies have tried to explain this novelty as changes in the developmental patterning of the mandibular arch, the rostralmost pharyngeal arch, at the molecular and cellular levels.

The vertebrates traditionally include the hagfish, which do not have proper vertebrae due to their loss in evolution, though their closest living relatives, the lampreys, do. Hagfish do, however, possess a cranium. For this reason, the vertebrate subphylum is sometimes referred to as "Craniata" when discussing morphology.

The vertebrate skeletal system has paramount importance for analyses in evolutionary biology.
